Limitation (<8ppb) as well as excess (>150ppb) of available Ni reduces the methanogenic capacity to consume H<sub>2</sub>. We have compared the growth of three different methanogenic species in growth medium where Ni is either depleted or in excess. The H<sub>2</sub> threshold in an optimal growth medium was two orders of magnitude lower (0.7 p<sub>H<sub>2</sub></sub>) than in the medium with Ni limitation or excess (35 p<sub>H<sub>2</sub></sub>). No significant differences in CH<sub>4</sub> production could be detected. This implies that Ni stress limits the methanogenic ability to grow in environments with low H<sub>2</sub> concentrations. In terms of survival of microorganisms in the deep subsurface, a very low p<sub>H<sub>2</sub></sub> would be expected due to the slow alteration rates of H<sub>2</sub> producing minerals at the low temperatures needed to sustain microbial growth. Our study shows that Ni is essential for keeping the p<sub>H<sub>2</sub></sub> low, indicating that any natural H<sub>2</sub> driven systems has to either supply high Ni concentrations and/or high H<sub>2</sub> concentrations in order to sustain a methanogenic culture. A deep subsurface environment where the Ni is relatively high would allow methanogenic cultures to sustain even with slow releases of H<sub>2</sub> from water-rock interactions.
