Magnesium ions ( $\text{Mg}^{2+}$ ) affect the  $\text{CaCO}_3$  crystal nucleation, morphology and growth/dissolution rate. Recently, the relation of hydration and these phenomena has been suggested. In this study, we conducted the three-dimensional (3D) observation of water distribution in the vicinity of calcite surface by using the frequency modulation atomic force microscopy (FM-AFM). We compared the molecular-scale change of water distribution in 100 mM  $\text{Ca}^{2+}$ ,  $\text{Sr}^{2+}$  and  $\text{MgCl}_2$  solutions to specify the effect of  $\text{Mg}^{2+}$  on water.

The eigenfrequency of silicon probe is shifted by the interactions with the surface atom and the water molecules in the vicinity of sample surface. The 2D/3D maps of frequency shift ( $\Delta f$ ) represent the water density distribution namely hydration structure.

The 3D  $\Delta f$  maps revealed the characteristic change in the lateral water distribution in the 1<sup>st</sup> hydration layer in  $\text{MgCl}_2$  solution. Analysing 3D water distribution, the hydration structures in  $\text{CaCl}_2$  and  $\text{SrCl}_2$  solutions were strongly affected by the calcite structure. However, the water in  $\text{MgCl}_2$  solution was formed bcc structure. This structure was consistent with the 6 coordination of the 1<sup>st</sup> hydration shell of single magnesium ion. This result suggest that the  $\text{Mg}^{2+}$  distribute in the hydration layers of calcite surface. A previous MD simulation have reported that the  $\text{Ca}^{2+}$  distribute the out of the hydration layers of calcite surface compared with the monovalent ions [Ricci et al. (2014)]. On the other hand,  $\text{Mg}^{2+}$  may distribute in the hydration layers due to its lower hydration energy than  $\text{Ca}^{2+}$  and  $\text{Sr}^{2+}$ . This specific effect of  $\text{Mg}^{2+}$  on hydration structure strongly suggest the effects of hydration on the calcite growth and polymorphism.
