A time-series of dissolved $^{230}$Th from 1991 to 2015 enables identifying processes that control the temporal development of $^{230}$Th distributions in the Amundsen Basin. After 2007, $^{230}$Th concentrations decreased significantly over the entire water column, particularly between 300 m and 1500 m. This decrease is accompanied by a circulation change, indicated by an increase of salinity. Potentially increased inflow of water of Atlantic origin with low dissolved $^{230}$Th concentrations leads to the observed depletion in dissolved $^{230}$Th in the central Arctic. Since atmospheric tracers (CFC, $^3$He/$^4$H) do not show increased ventilation rates, these interior waters must have undergone enhanced scavenging of Th during transit from Fram Strait and the Barents Sea to the Amundsen Basin. The $^{230}$Th depletion propagates downward in the water column by settling particles and reversible scavenging.
