Peat areas in south central Iceland receive huge amounts (500-800 gm⁻²yr⁻¹) of fine-grained basaltic glass dust during storm events [1]. These dust particles are in the size range of 100 to 1 µm [1] yielding a high reactive surface area load, which is comparable to those suggested for enhanced rock weathering (ERW) field experiments [2].

We sampled soil solutions in a histic andosol soil that commonly consists of less than 20 % organic matter and huge amounts of basaltic glass in south central Iceland. Suction cups and Rhizon samplers were inserted at 10-260 cm depth within the soil. The pH and alkalinity increased with depth while the solutions became more reduced. The pH ranged from 5.5-6.7. At the highest pH, about half of the dissolved inorganic carbon was present as bicarbonate (HCO₃⁻).

The pH is a direct result of the combination of two natural processes: (1) decomposition of organic matter and (2) weathering of basaltic glass. Fast dissolution rate of the basaltic glass is maintained by the formation of allophane (Al₂O₃SiO₂(H₂O)₂.₅), which keeps the Al³⁺ activity low in the entire soil body. In addition, iron precipitated under oxic and reduced conditions as ferrihydrite (Fe(OH)₃) or siderite (FeCO₃), respectively. Simultaneously, sulphur and heavy metal concentrations decreased with depth, where siderite and mackinawite (FeS) were close to saturation. According to reaction path modelling the mass of dissociation of organic carbon within the soil solutions was 4 mmol/kg while the basaltic glass dissolution was estimated to be 1.2 mmol/kg.

These results indicate a higher CO₂ solubility and mineral storage of the Icelandic peat soil studied here compared to other peat areas receiving only limited fine-grained air born basaltic glass dust.
