*Adamussium colbecki* is a large thin-shelled scallop common in Antarctic waters and well represented throughout the Holocene. Shell nitrogen isotopes in carbonate bound organic matter (δ¹⁵N<sub>CBOM</sub>) have the potential to record sea ice state over time. Recent studies illustrated that δ¹⁵N<sub>CBOM</sub> values provide a similar proxy as soft tissue δ¹⁵N values which in turn are predictably related to food δ¹⁵N values [1]. Sea-ice organic N should have higher δ¹⁵N values compared to open water organics due to nitrate draw down in the ice [2]. To test this hypothesis, we analyzed *A. colbecki* shells from Explorers Cove and Bay of Sails, western McMurdo Sound, Antarctica. These sites have different sea ice states: persistent (multiannual) sea ice at Explorers Cove and annual sea ice (that melts out every year) at Bay of Sails. Six adult shells collected live at these sites in 2008 (3 from each site) and two juveniles collected in 2016 from Explorers Cove were serially sampled for δ¹⁵N<sub>CBOM</sub> values from the growing shell margin to the umbo. δ¹⁵N<sub>CBOM</sub> values from Explorers Cove with persistent sea ice cover were consistently higher (+10 ± 0.7 ‰) than those from Bay of Sails where the sea ice melts out every year (+8 ± 0.5 ‰; t-test p<0.0001). δ¹⁵N<sub>CBOM</sub> data from Mid- to Late Holocene shells that grew in these locations will also be presented. We posit that nitrogen isotopes in *A. colbecki* shells have a high potential to record sea ice cover.
