The Himalayan orogeny has been long thought to be a driver of Cenozoic cooling due to its capacity to sequester atmospheric CO₂ by silicate weathering and organic burial, which significantly exceeds the CO₂ release by other weathering processes such as sulfuric acid-induced carbonate weathering and rock organic matter oxidation. However, the impact of deep carbon fluxes, viz. mantle sources such as magmatic volatilization or crustal sources such as metamorphic decarbonation, oxidation of sedimentary organic matter, and aqueous carbonate dissolution on the carbon cycle, is poorly constrained. In this study, we quantified the CO₂ fluxes released from geothermal springs to the atmosphere through fault zones. A Rayleigh fractionation-based model that utilizes the geothermal discharge and the temperature, dissolved inorganic carbon (DIC) concentrations, and δ¹³C composition of DIC (δ¹³C_DIC) in hot spring waters and δ¹³C of degassed CO₂ (δ¹³C_CO₂) was used to quantify the CO₂ degassed from hot springs. This direct CO₂ flux was combined with diffuse soil CO₂ flux estimates to arrive at deep CO₂ flux estimates for the entire orogen. We show that the Himalayan-Tibetan orogen can release an order of magnitude of 10¹¹ mol C yr⁻¹, which is comparable to major geological carbon sources such as continental rifts, volcanoes, and mid-oceanic ridge as well as the CO₂ drawdown due to silicate weathering in the orogen (~3.4 x 10¹¹ mol C yr⁻¹), thereby significantly counteracting the latter. Furthermore, a CO₂/³He – δ¹³C_CO₂ mixing model in geothermal gases was used to separate crustal and mantle contributions. On the other hand, ionic concentrations in hot springs determined the proportion of the crustal contributions derived from carbonate dissolution, with the rest being metamorphic. Our analysis reveals that metamorphism is the primary source of the degassed CO₂ (65%), followed by aqueous carbonate dissolution (28%) and the mantle (7%). We conclude that this additional flux of CO₂ will more than halve the orogen’s carbon sink and potentially turn it into a net carbon source. Thus, on million-year timescales, deep carbon releases will offset the impact of the carbon sink created by weathering processes and mute the orogeny’s role in regulating long-term climate change.
